I. Introduction

A complete understanding of the physical processes underlying the transition between the high-temperature exponential relaxation of density fluctuations of a fluid and the nonexponential relaxational profiles observed at lower temperatures, especially near the glass transition, remains elusive. A number of interesting features have been noted in dense, supercooled systems from computer simulation studies\(^1\)\(^–\)\(^2\) as well as multidimensional NMR\(^8\)\(^–\)\(^9\) and video microscopy experiments\(^10\)\(^,\)\(^11\) that appear to be related to this crossover from simple exponential to multiexponential or stretched exponential relaxation: One typical feature of such systems is the appearance of heterogeneously distributed regions of the fluid which differ dramatically in their mobility and local density. While fluid motions are relatively unrestricted in regions of low density, structural rearrangements in regions of high local density at a given time have been observed to occur through relatively rapid, collective stringlike motions.\(^1\) Furthermore, regions which at one point contained in the subensemble necessarily involve multiple-time correlation functions of collective densities (i.e., particle number, momentum and energy densities). The theory is extended here to include tagged particle densities. Such densities have found an intriguing application as proposed measures of dynamical heterogeneities in structural glasses. The theoretical formalism is based upon projection operator techniques which are used to isolate the slow time evolution of dynamical variables by expanding the slowly evolving component of arbitrary variables in an infinite basis composed of the products of slow variables of the system. The resulting formally exact mode-coupling expressions for multiple-point and multiple-time correlation functions are made tractable by applying the so-called \(N\)-ordering method. This theory is used to derive for moderate densities the leading mode coupling expressions for indicators of relaxation type and domain relaxation, which use dynamical filters that lead to multiple-time correlations of a tagged particle density. The mode coupling expressions for higher order correlation functions are also successfully tested against simulations of a hard sphere fluid at relatively low density.

The theoretical framework for higher-order correlation functions involving multiple times and multiple points in a classical, many-body system developed by Van Zon and Schofield [Phys. Rev. E 2002, 65, 011106] is extended here to include tagged particle densities. Such densities have found an intriguing application as proposed measures of dynamical heterogeneities in structural glasses. The theoretical formalism is well-established. In this article, the theory is extended to include multiple-time correlation functions of tagged particle densities, but with different rates, so that the observed nonexponentiality is a consequence of the superposition of different exponential relaxation processes. Of course neither scenario may apply over all time scales and the mechanism may shift from one that is primarily homogeneous to one that is primarily heterogeneous. It is equally possible that one type of relaxation may not even predominate over another.

To distinguish between these scenarios, it is helpful to construct quantitative measures which unambiguously signal the presence of a specific mechanism. Such constructions can be based on filters\(^8\)\(^–\)\(^12\)\(^–\)\(^14\) that select out subensembles of particles to have specific dynamical properties over a sampling period. A simple example of such a filter is one that selects out individual particles that move either more or less than a critical distance over a fixed period of time. One can then examine time correlations within these subensembles to gain new insight into detailed features of the dynamics. When time-filters are utilized in this fashion, time correlation functions of particles contained in the subensemble necessarily involve multiple-time intervals. Filters based on single-particle properties then can be expressed as multiple-time correlation functions of tagged particle densities.

Given this interesting application of multiple-time correlation functions, the need for a theory that enables one to calculate such quantities from first principles is clear. In ref 15, such a theory was developed based on mode-coupling theory for multiple-time correlation functions of collective densities (i.e., particle number, momentum and energy densities). The theory was tested successfully on a hard sphere gas at moderate densities in the hydrodynamic limit where the relevance of mode-coupling theory is well-established. In this article, the theory is extended to include multiple-time correlation functions of arbitrary type, encompassing correlation functions involving...
The paper is organized as follows: The mode-coupling formalism of multiple-time correlation functions is introduced in section II based on projection operator methods, and equations describing the evolution of multiple-point densities of arbitrary type are obtained. These equations are manipulated to yield expressions for correlation functions of multiple-time intervals that are local in all time arguments. In section III, a systematic method of determining what types of contributions are the most significant for a particular multiple-time interval correlation function of tagged particle densities is introduced and the leading-order expressions for two- and three-time interval correlations of a tagged particle density are presented. In section IV, specific applications of multiple-time correlation functions of tagged particle densities are examined. In particular, direct measures of relaxation type and of the rate at which solidlike domains become fluidized are analyzed and leading order mode-coupling expressions for these measures are obtained. Section IV concludes with a numerical comparison of the leading order theoretical predictions with direct simulation results for a low density, hard sphere system in the hydrodynamic limit, and section V contains a summary.

II. Mode-Coupling Formalism

A. Slow Variables. The basic assumption of mode-coupling theory is that the long time behavior of all time correlations functions can be completely expressed in terms of the evolution of a set of slow modes of the system. Although the theory does not specify the identity of the slow modes, physical arguments can often serve as a guide to define a finite set of variables that serve as a dynamical basis for the long time evolution. For example, since the particle number, the momentum, and the total energy of a fluid of structureless particles are constants of motion, a minimal basis set for the slow evolution of the system must include the long wavelength modes of densities of these quantities.

Once the slow basis set has been determined, the slow component of an arbitrary dynamical quantity can be extracted by finding the projection of the variable onto the subspace spanned by the set of slow variables. Similarly, projecting the variable onto the complement of this subspace should yield a fast quantity.

Projection operators are linear operators, and hence only the linear dependence of a dynamical variable on the slow variables can be projected out by such a procedure. In general, however, one expects the time dependence of most dynamical variables to be a nonlinear function of the slow variables. This nonlinearity can be incorporated into the theory by constructing the slow subspace to include the space spanned by all powers of the slow variables. In this way, an analytic dependence of the slowly evolving component of a dynamical variable on the slow variables can be described. The basis of the slow subspace is referred to as the multilinear basis.

Consider an equilibrium system composed of \( N \) particles that is described by a translationally invariant Hamiltonian \( \hat{H} \). The time evolution of any quantity (phase space function) \( C \) is given by

\[
\dot{C}(t) = L C(t)
\]

with \( L \) the Liouvillian operator, which is the Poisson bracket with the Hamiltonian.

To describe the slow evolution of dynamical variables within the projection operator formalism, the slow variables of the system are taken together in a single vector \( \mathbf{B} \). As mentioned above, for a structureless fluid, these are typically the number density, the momentum density, and the energy density:

\[
B(\mathbf{r}, t) = \begin{pmatrix}
N(\mathbf{r}, t) \\
\mathbf{P}(\mathbf{r}, t) \\
E(\mathbf{r}, t)
\end{pmatrix} = \begin{pmatrix}
\sum_{n=1}^{N} \delta(\mathbf{r} - \mathbf{r}_n(t)) \\
\sum_{n=1}^{N} \mathbf{p}_n(t) \delta(\mathbf{r} - \mathbf{r}_n(t)) \\
\sum_{n=1}^{N} \epsilon_n(t) \delta(\mathbf{r} - \mathbf{r}_n(t))
\end{pmatrix}
\]

Here, \( \mathbf{r}_n(t) \) is the position of particle \( n \) at time \( t \), \( \mathbf{p}_n(t) \) is its momentum and \( \epsilon_n(t) \) its energy (kinetic and potential). It will be convenient to work in Fourier space:

\[
\mathbf{B}(\mathbf{k}, t) = \sum_{n=1}^{N} e^{i \mathbf{k} \mathbf{r}_n(t)} b_n(t)
\]

where \( b_n(t) = (1, \mathbf{p}_n(t), \epsilon_n(t)) \).

Since the goal of the mode-coupling theory outlined here is to describe the time correlation functions of single particles, slow tagged particle densities must be included, i.e.

\[
N_1(\mathbf{r}, t) = \delta(\mathbf{r} - \mathbf{r}_1(t))
\]

where particle 1 is the tagged particle. In the Fourier representation, the tagged particle number density is simply

\[
N_1(\mathbf{k}) = e^{i \mathbf{k} \mathbf{r}_1(t)}
\]

The tagged particle density is taken together with \( \mathbf{B}(\mathbf{k}) \) into a larger vector \( \mathbf{A}(\mathbf{k}) \). Henceforth, components of \( \mathbf{A}(\mathbf{k}) \) will be denoted with a superscript \( s \) when referring to single particle densities (which have no summation over particles in their definition) and with a superscript \( c \) when involving collective densities (which have a summation over all particles in their definition).

We require that the slow subspace be spanned by all powers of the slow variables. Since the product \( N_1(\mathbf{k})N_1(\mathbf{q}) = N_1(\mathbf{k} + \mathbf{q}) \) is just a linear variable, beyond the linear level only products of \( \mathbf{B} \) are relevant. Furthermore, to accommodate correlation functions of certain fast variables one might be interested in (e.g., \( \mathbf{P}_1(\mathbf{k}) = \mathbf{p}_1(t) e^{i \mathbf{k} \mathbf{r}_1(t)} \)), \( \mathbf{A}(\mathbf{k}) \) is defined as the vector composed of all linear slow variables plus any fast variables of interest.

It will prove to be convenient to construct a basis set that is orthogonal in the number of factors of the linear set \( \mathbf{A} \) and \( \mathbf{B} \), which is guaranteed by the definition

\[
Q_0 \equiv 1
\]

\[
Q_1(\mathbf{k}) \equiv A'(\mathbf{k}) - \langle A'(\mathbf{k}) \rangle = \hat{A}(\mathbf{k})
\]

\[
Q_2(\mathbf{k}_1, \mathbf{k}_2) \equiv \hat{A}(\mathbf{k}_1) \hat{B}(\mathbf{k}_2)
\]

\[
- \sum_{|\alpha|=0}^{1} \langle \hat{A}(\mathbf{k}_1) \hat{B}(\mathbf{k}_2) \rangle Q_\alpha^* K_{\alpha \alpha}^{-1} * Q_\alpha
\]

Here the following notation has been used:

- \( \langle \cdots \rangle \) denotes the (grand canonical) equilibrium ensemble average, which is used to define the inner product.
- A superscript "*" defines complex conjugation.
... A Greek lower case letter denotes a set of pairs, each pair containing a component index and a wave vector.

* | denotes the number of pairs in the set α, the so-called mode order.

- A hatted Greek letter has the same mode order as its unhatted variant but is otherwise unrelated.
- \( Q_{\alpha} \) is the same as \( Q_{\alpha}(k_1, ..., k_{|\alpha|}) \). Also, in the rest of the paper, the short hand notation of a number \( n \) instead of a Greek letter will often be used to indicate a set of mode order is \( n \).
- The "*" product involves a summation over the pairs of wave vectors and indices in \( \alpha \), divided by all ways in which these pairs can be permuted, so as to avoid overcounting. Also, for this summation to always be well-defined, the wave vectors will often be used to indicate a set of mode order is \( n \).
- The "*" product involves a summation over the pairs of wave vectors and indices in \( \alpha \), divided by all ways in which these pairs can be permuted, so as to avoid overcounting. Also, for this summation to always be well-defined, the wave vectors will often be used to indicate a set of mode order is \( n \).

By definition, \( K_{\alpha\beta} \equiv \langle Q_{\alpha} Q_{\beta}^* \rangle \), while \( K^{-1} \) is the inverse of this object with respect to the "*" product.

As the definition of \( Q_{\alpha} \) contains \( K_{\alpha\alpha} \) for all \( m < n \), which are defined using the \( Q_{m-n} \), the above definition of the nonlinear basis is basically recursive. Note that as \( K_{\alpha\alpha} = 0 \) if \( n \neq m \), the above set is orthogonal in mode order: \( K_{\alpha\alpha} = \langle Q_{\alpha} Q_{\alpha} \rangle = 0 \) unless \( n = m \).

We note also that \( \hat{N} I(k=0) = \text{exp}\{ikr\} - 1 - \delta k_0 \}_{k_0} = 0 \). This implies that \( \langle \hat{N} I(0), \hat{N} I(0) \rangle \rangle = 0 \), and, more importantly, that the elements \( Q_{\alpha} \) which have a \( N1 \) component with zero wave vector have to be omitted from the set to avoid an overcomplete basis.

### B. Single Time Interval Correlations.

Let all time correlation functions of the slow (linear) variables be taken together into the matrix

\[
G_{11}(t) = \langle Q_{\alpha}(t) Q_{\beta}^* \rangle \equiv K_{\alpha\beta}^{-1}
\]

Note that \( G_{11} \) is wave vector dependent, but that this is not explicitly denoted here.

To make contact with other versions of mode-coupling theory, we first examine the consequences of taking only the linear basis \( Q_1 \) into account. The time evolution of \( Q_1 \) is given by eq 1. In differential form, this means

\[
\dot{Q}_1(t) = L Q_1(t) = e^{L(t)} Q_1
\]

Defining the linear projection operator

\[
P_1 C \equiv \langle C Q_{\alpha}^* \rangle \equiv K_{\alpha\alpha}^{-1} \equiv Q_1
\]

and its complement \( P_1^\perp \equiv 1 - P_1 \), and using a well-known operator identity, eq 5 can be cast in the form of a generalized Langevin equation

\[
\dot{Q}_1(t) = M_{11}^E \dot{Q}_1(t) + \int_0^t \dot{M}_1(t - \tau) \dot{Q}_1(t) \, d\tau + \dot{\varphi}_1(t)
\]

in which a fluctuating force \( \dot{\varphi}_1(t) \equiv L P_1^\perp L Q_1 \), a static vertex \( M_{11}^E \equiv \langle L Q_1 Q_{\alpha}^* \rangle \equiv K_{\alpha\alpha}^{-1} \), and a memory kernel \( \dot{M}_1(t) \equiv -\langle \dot{Q}_1(t) Q_{\alpha}^* \rangle \equiv K_{\alpha\alpha}^{-1} \) appear. By taking the inner product with \( Q_1 \), eq 6 yields

\[
\dot{G}_1(t) = M_{11}^E G_1(t) + \int_0^t \dot{G}_1(t - \tau) \, d\tau
\]

It should be noted that because of translational symmetry, the sum of wave vectors in an average has to add up to zero. Thus, \( G_{11} \) involves only one wave vector, instead of two. Likewise, the above equation is an equation involving just one wave vector. In this sense, there is no mode-coupling in the above equation, although, of course, the different components of \( Q_1 \) are coupled.

The memory kernel \( \dot{M}_1(t) \) involves the time correlation of the fluctuating force \( \dot{\varphi}_1(t) \), for which the formalism as presented thus far provides no method of evaluating. However, provided \( P_1^\perp \) projects out all the slow behavior of \( \dot{\varphi}_1(t) \), \( \dot{\varphi}_1(t) \), which contains dynamics orthogonal to \( A \) only, should be a quickly decaying function that is well-approximated at long times \( t \gg t_m \) by \( \dot{M}_1(t) \approx 2D\dot{Q}(t) \), for some microscopic time \( t_m \) on the order of the particle–particle collision time. Under such circumstances, eq 7 is local in time, i.e., \( G_{11}(t) = (M_{11}^E + D) * G_1(t) \). Unfortunately, in most cases, the correlation function of the dissipative force \( \dot{\varphi}_1(t) \) is not a quickly decaying function but instead has long time tails due to the fact that the linear projection operator \( P_1^\perp \) does not remove the nonlinear dependence of \( \dot{\varphi}_1(t) \) on the set of slow variables \( B \). Hence, one is forced to use the full multidimensional basis if equations of motion are to be local in time.

In the following, \( Q \) will denote the vector composed of all \( Q_{\alpha} \). As \( Q \) is still a phase space function, its time evolution is governed by

\[
\dot{Q}(t) = L Q(t)
\]

Using the multilinear projection operator

\[
P_C \equiv \langle C Q_{1}^* \rangle \equiv K_{11}^{-1} \equiv Q_1
\]

(where the "*" now also denotes a sum over mode orders) and its complement \( P_1^\perp \equiv 1 - P_1 \), an equation analogous to eq 7 is found

\[
\dot{G}(t) = M_{01}^E G(t) + \int_0^t M_0^P(t - \tau) \, d\tau \equiv \dot{G}(t)
\]

where \( G(t) \) is the full propagator defined by

\[
G(t) \equiv \langle Q(t) Q^{*} \rangle \equiv K_{11}^{-1}
\]

the fluctuating force is defined by

\[
\dot{\varphi}(t) \equiv e^{P_1^\perp L P_1^\perp} L Q(t)
\]

and the vertexes \( M_{01}^E \) and \( M_0^P(t) \) are given by

\[
M_{01}^E \equiv \langle L Q_1 Q_{\alpha}^* \rangle \equiv K_{\alpha\alpha}^{-1}
\]

\[
M_0^P(t) = -\langle \dot{Q}(t) Q_{\alpha}^* \rangle \equiv K_{\alpha\alpha}^{-1}
\]

Note that the original goal of evaluating \( G_{11}(t) \) now becomes to calculate the \( 1-1 \) (or linear–linear) sub-block of \( G(t) \) while \( G_{1\alpha}(t) = G_{\alpha\alpha}(t) = \delta_{\alpha\alpha} \) is trivial.

Now that all powers of \( B \) are projected out of the dynamics, one expects \( \dot{\varphi} \) to be truly fast, and its correlation function to be approximately a \( \delta \) function. Defining the dissipative vertex as

\[
M_{01}^D \equiv \int_0^\infty M_{11}^D(t) \, dt
\]

and the full vertex to be

\[
M \equiv M_{01}^E + M_{01}^D
\]

we can write

\[
\dot{G}(t) = M * G(t)
\]

as an approximation to eq 8.
A physical note is in order here: it is assumed that there is a separation of time scales, such that there are fast correlations which decay on the short microscopic scale \( t_m \), while the interesting long time behavior occurs on slow, “hydrodynamic” scales \( t_h \), and we assume \( t_m \ll t_h \). Equation 12 describes just the slow part, so it is valid only after a time (much) larger than \( t_m \) with corrections of order \( O(t_m/t_h) \).

It is useful to perform a Laplace transform:

\[
G(z) = \int_0^\infty e^{-zt}G(t) \, dt
\]

With the initial condition \( G_{a|\beta}(t=0) = \delta_{a|\beta} \) (the unit matrix in infinite dimensions), eq 12 can be solved formally in Laplace space,

\[
G(z) = [z - M]^{-1}
\]

where the inverse is to be taken with respect to the “*” product. By splitting up the matrix \( M_{a|\beta} \) into its part diagonal in wave vectors \( M^d \) (i.e., the wave vectors in \( \alpha \) and \( \beta \) are pairwise equal) and an off-diagonal remainder, \( M^o = M - M^d \), one can write

\[
G(z) = [z - M^d - M^o]^{-1} = G^d(z) \ast [1 - M^o G^d(z)]^{-1}
\]

(13)

where the bare, mode-order diagonal propagator \( G^d \) is defined as

\[
G^d(z) \equiv [z - M^d]^{-1}
\]

Because the wave vectors in \( \alpha \) and \( \beta \) have to pair up in \( M_{a|\beta} \), the numbers of wave vectors \( |\alpha| \) and \( |\beta| \) need to be equal as well, i.e., \( M^d \) and \( G^d \) are also diagonal in mode order. \( G^d(z) \) at a particular mode-order \( n \) is denoted as \( G^d_n(z) \).

The inverse in eq 13 can be expanded to yield

\[
G(z) = G^d(z) + G^d(z) \ast M^o \ast G^d(z) + G^d(z) \ast M^o \ast G^d(z) \ast M^o \ast G^d(z) + \ldots
\]

(14)

The 1–1 element of \( G(z) \) can be written in terms of a self-energy that is defined as

\[
\Sigma(z) \equiv \sum_{n=2}^{\infty} M^o_{1n} \ast G^d_n(z) \ast M^o_{nm} + \ldots
\]

(15)

Note that the summations start at mode-order 2. After re-summing eq 15, \( G_{11}(z) \) is related to \( \Sigma(z) \) by

\[
G_{11}(z) = [z - M_{11} - \Sigma(z)]^{-1}
\]

(16)

This result can be compared to the solution in Laplace space of eq 7, \( G_{11}(t) = [z - M_{11}^o - M(z)]^{-1} \). Thus, the self-energy is related to the memory kernel by

\[
\tilde{M}(z) = M_{11}^0 + \Sigma(z)
\]

(17)

Since \( M_{11}^0 \) is short-lived, the long time tails of the memory function are due to mode-coupling effects in \( \Sigma(z) \).

It was shown by Schofield and Oppenheim that in the thermodynamic limit, the series for the self-energy for \( \Sigma \) can be re-summed, with the result that all bare propagators in eq 15 are replaced by propagators that are completely diagonal in wave vector, but with the restriction of the sum over intermediate wave vector sets that none of them should be equal. In the same paper, it was shown that that these full diagonal multilinear propagators factor in the thermodynamic limit into products of full linear—linear propagators. As a result, eqs 15 and 16 combine to a self-consistent equation for \( G_{11}(z) \). It should be noted that although the formalism assumes the diagonal mode order and wave vector multiple-point correlation functions factor into products of full linear—linear correlation functions, this factorization is not equivalent to assuming that the basis set variables behave as Gaussian random variables. The factorization here occurs only for fully “diagonal” wave vector indices, and off-diagonal components of a multiple-point functions are included through mode-coupling expressions. For example, the off-diagonal part of \( G_{22}(k - q, q; k - q', q') \) with \( q \neq q' \) and \( k - q \neq q' \) is represented by the series in Laplace space

\[
G_{22}(k - q, q; k - q', q') = G_{22}^d(k - q, q; z)M_{22}^o(k - q, q; z) + \ldots
\]

(18)

It can be shown that corrections to the factorization of the fully diagonal multiple-point correlation functions vanish in the thermodynamic limit provided the (time-dependent) dynamical correlation length is nonextensive. These results rely on the \( N \)-ordering technique, which will be discussed in detail in section III.

C. Multiple-Point Correlations. In ref 15, the functions \( G_{a|\beta}(t) \) with either \(|\alpha| \) or \(|\beta| \) bigger than one were called multiple-point correlation functions because they can be seen as Fourier transforms of correlation function of densities involving more than one relative position. Note that if \(|\alpha| = |\beta| \) and the wave vectors in \( \alpha \) and \( \beta \) are fully (pairwise) matched, \( G_{a|\beta} \) is the full propagator at mode-order \(|\alpha| \), and this propagator can be written as a product of full-linear propagators to an excellent approximation. However, even when the wave vectors are not fully matched, \( G_{a|\beta} \) is still an interesting but nontrivial quantity.

The expression for the multiple-point correlation functions follows from the general form in eq 14. The form of the equation is identical to the case of just collective densities that was treated in ref 15 (section II.D). By performing the same re-summations, which rely on the \( N \)-ordering method to be discussed shortly, one obtains the result of eq 26 of that paper:

\[
G_{a|\beta} = G_{aa} \delta_{a|\beta} + G_{aa} \ast M_{a|\beta}^o \ast G_{\beta|\beta} + G_{aa} \ast M_{a|\beta}^o \ast G_{\beta|\beta} \ast M_{\beta|\beta}^o \ast G_{\beta|\beta} + \ldots
\]

(19)

Here, primed Greek indices have the same wave vectors as their unprimed variants, but not necessarily the same component indices, i.e., they are fully diagonal in wave vector. Thus, \( G_{aa} \delta_{a|\beta} \) denotes the full diagonal in wave vector of the propagator at mode-order \(|\alpha| \), and \( G_{aa} \ast M_{a|\beta}^o \ast G_{\beta|\beta} \ast M_{\beta|\beta}^o \ast G_{\beta|\beta} + \ldots \) expresses the multiple-point correlation function in terms of the full propagators, which can be expressed in terms of the full linear—linear propagators. By using \( N \)-ordering (see section III), one can show that contributions in eq 19 involving \( G_{a|\beta} \) with \( n < |\alpha| \) and \( n < |\beta| \) are negligible in the thermodynamic limit.

D. Multiple-Time Correlations. The results above consider only correlation functions that contain a single time interval. However, the case of correlation functions of several time
intervals, which in general will be denoted (following ref 15) by $G^{(0)}_{\alpha_{i},...\alpha_{n}}(t_{n},t_{n-1},...t_{1})$ or

$$G^{(0)}_{\alpha_{i}}(\{t_{j}\}) \equiv \langle Q_{\alpha_{i}}(t_{1}) ... Q_{\alpha_{i}}(t_{j}) \rangle * K_{\alpha_{i} \alpha_{i}}^{-1}$$

is of considerable interest.

Even very straightforward approaches to multiple-time correlation functions lead to expressions involving multiple-time correlations of the fluctuating force. Such correlation functions are generally nontrivial as they are not always fast decaying.20

The essential ingredient in deriving mode-coupling expressions for multiple-time correlation functions, as remarked in ref 15, is that “in a correlation function involving fluctuating forces, the function decays quickly in a pair of time arguments, provided these are well-separated in time.” Here, “well-separated” means having a time separation much larger than the microscopic time scale $t_{m}$ on which $q_{i}(t) q_{j}^{*}$ decays. For correlation functions of collective densities, this argument led to the conclusion that a correlation function involving several time arguments $t_{i}$ whose time evolution arises through the fast evolution operators expressed in $P^{+}L_{i}$ can be considered fast-decaying in each of the times $t_{i}$ provided all times are positive, larger than $t_{m}$, and the evolution operators are applied in succession. When these properties hold, all effective times (such as $t_{1}, t_{1} + t_{2}, t_{1} + t_{2} + t_{3},$ etc.) are well-separated and the quoted criterion applies.

On a formal level, the arguments invoked in ref 15 to derive expressions for multiple-time correlation functions of collective densities apply equally well when tagged particle densities are included in the slow basis set. Thus, by using projection operator techniques, the following relation can be established:

$$G^{(n)}_{\alpha_{i},...\alpha_{n}}(\{t_{j}\}) = \int_{0}^{\infty} d\tau_{1} \int_{0}^{\infty} d\tau_{n} G_{\alpha_{i},...\alpha_{n},\alpha_{j}}(\tau_{n},\tau_{1}) \times$$

$$G^{(n-1)}_{\beta_{j},\beta_{j-1},...\beta_{1}}(\tau_{n-1},...,\tau_{1},\tau_{n-2},... \tau_{1}) \quad \text{with}$$

$$M_{\beta_{j},\beta_{j-1}}(\tau_{n},\tau_{1}) = 4\langle Q_{\beta_{j}}(t) Q_{\beta_{j-1}}(t) \rangle K_{\beta_{j},\beta_{j-1}}^{-1} \delta(\tau_{n}-\tau_{1})$$

In the limit of long times when $\tau_{1} \gg t_{m}$, the fast term can be neglected and the integral can be replaced by a $\delta$ function according to the above criterion, yielding an equation that is local in $t_{n}$

$$G^{(n)}_{\alpha_{i},...\alpha_{n},\alpha_{j}}(\tau_{n}) = G_{\alpha_{i},...\alpha_{n},\alpha_{j}}(\tau_{n}) * M_{\beta_{j},\beta_{j-1}}(\tau_{n},\tau_{1}) * G^{(n-1)}_{\beta_{j},\beta_{j-1},...\beta_{1}}(\tau_{n-1},...,\tau_{1},\tau_{n-2},... \tau_{1})$$

where $M_{\beta_{j},\beta_{j-1}} = \int_{0}^{\infty} d\tau_{1} \int_{0}^{\infty} d\tau_{n} M_{\beta_{j},\beta_{j-1}}(\tau_{n},\tau_{1})$. Different from the single time correlations of sections IIIB and IIC, where including $Q_{\beta}$ was of little practical consequence, for the multiple-time correlations here it may happen that $|\beta|$ or $|\beta|$ is zero. For these special cases, $M_{\beta_{j},\beta_{j-1}}$ are given by $M_{\beta_{j},\beta_{j-1}} = K_{\beta_{j},\beta_{j-1}}$ and $M_{\beta_{j},\beta_{j-1}} = M_{\beta_{j},\beta_{j-1}}$.

The recursion relation in eq 21 can be applied as many times as necessary to yield a relation between $G^{(n)}$ and $G^{(1)}$. For instance, for $n = 2$ and $n = 3$:

$$G^{(2)}_{\alpha_{i},\alpha_{j}}(t_{1},t_{2}) = G^{(2)}_{\alpha_{i},\alpha_{j}}(t_{1}) * M_{\alpha_{i},\alpha_{j}} * G^{(1)}_{\alpha_{j}}(t_{1})$$

$$G^{(3)}_{\alpha_{i},\alpha_{j},\alpha_{k}}(t_{1},t_{2},t_{3}) = G^{(3)}_{\alpha_{i},\alpha_{j},\alpha_{k}}(t_{1}) * M_{\alpha_{i},\alpha_{j}} * G^{(2)}_{\alpha_{j},\alpha_{k}}(t_{2}) * M_{\alpha_{k},\alpha_{j}} * G^{(1)}_{\alpha_{j}}(t_{1})$$

III. N-Ordering Scheme for Tagged and Mixed Correlations

To make the infinite series such as in eq 15 or in eq 21 tractable, one must develop a systematic scheme for analyzing the relative importance of terms appearing in the series. In such an approach, the series must be analyzed so that simple but accurate approximations for the entire series can be formulated in a (preferably) controlled fashion. The N-ordering method, developed by Oppenheim and co-workers 21,22 as an extension of Van Kampen’s system size expansion, 23 allows such an approach for correlation functions on the hydrodynamic length scale in systems of moderate density removed from any critical point. In the N-ordering approach, one assigns a factor of $N$ (the number or average number of particles) to any cumulant of multimode densities based on the assumption that the each cumulant containing $n$ linear densities scales with the system size as $N^{(\frac{n}{2})}$, where $\xi$ is the correlation length of the system and $a$ is the average distance between particles. As shown in ref 19, the N-order of an arbitrary correlation function of basis functions $K_{\alpha\alpha} = \langle Q_{\alpha} Q_{\alpha} \rangle$ depends on the nature of the densities and the number of matched wave vectors in the sets $\alpha$ and $\alpha$. The subscripts like $\alpha = \{A_{i}(k-q_{1} - ... - q_{|\alpha|-1}), B_{1}(q_{1}), ..., B_{|\alpha|-1}(q_{|\alpha|-1} - 1)\}$ denote sets of wave vector-dependent densities, where each $B_{i}$ is a component of the set of collective slow variable defined in eq 2 and $A_{i}$ is a component of the extended linear basis set $A_{i}$. If the component $A_{i}$ in the set $\alpha$ is a single particle density, we denote the corresponding multimode density by a superscript $s$, $Q_{s}^{\alpha}$; if this component is a collective density, then the dynamical variable is represented by $Q_{c}^{\alpha}$. In ref 19, it was demonstrated that the leading N-order terms arise from matching as many wave vectors as possible in the sets $\alpha$ and $\alpha$, yielding the following estimates for $K_{\alpha\alpha}$.

$$K_{\alpha\alpha}^{cc} \sim N^{|\alpha|} \quad K_{\alpha\alpha}^{sc} \sim N^{|\alpha|-1} \quad K_{\alpha\alpha}^{cs} \sim N^{|\alpha|} \quad K_{\alpha\alpha}^{ss} \sim N^{|\alpha|-1}$$

where, for example, the superscript “ss” denotes that both sets $\alpha$ and $\alpha$ contain a single particle density. More importantly, it was also demonstrated that the N-order of $K_{\alpha\alpha}^{ss}$ only when the single particle densities are in the same matched set, and the N-order drops by a factor of $N$ when the wave vectors of the single particle densities do not match.

For the inverse of $K$, the N ordering in eq 23 implies

$$K_{\alpha\alpha}^{cc} \sim N^{-|\alpha|} \quad K_{\alpha\alpha}^{sc} \sim N^{-|\alpha|} \quad K_{\alpha\alpha}^{cs} \sim N^{-|\alpha|-1} \quad K_{\alpha\alpha}^{ss} \sim N^{-|\alpha|+1}$$

When considering the N order of an expression that contains the “*” product, one needs to separately consider its order in $M$ (the number of wave vectors summed over, see the seventh point at the end of section II). That is, when the “*” product is between multindices of order $n$, one has in principle $n!$ sums over wave vectors and thus an effective factor of $M^{-n!}$ (one loses one sum over a wave vector because by translation symmetry all wave vectors have to add up to zero inside an average). Although $M$ is of order N, these orders of $M$ are counted separately from the N ordering, for the following good reason: For fluids of moderate density only a small fraction of the wave vectors in the sums really contributes significantly. Therefore, rather than taking $M$ as counting the precise number of wave vectors summed over, it makes more sense to take $M$ as the number of wave vectors that contribute substantially to the sum. This results in a small value of $M$ which is nonetheless still $O(N)$. The $O(1)$ parameter $M/N$ is called the mode-coupling
parameter. As stated, it is typically small (e.g., $10^{-5}$) for fluids of moderate density and away from any critical point.

To illustrate this, consider for instance $K_{31}^M * K_{31}^M$, which is seen to have an $N$-ordering of $O(N^3)$. There is a possible summation over $M$ wave vectors in $K_M^M * K_M^M$, but in fact the leading order estimate of $O(N^3)$ requires a matching of wave vectors which gets rid of the factor $M$. As a result, the leading term of $K_{31}^M * K_{31}^M$ is just $O(N^3)$, with (possible) correction terms of order $O(MN^3)$, which compared to the leading term are of relative order $MN/1$, i.e., of the mode coupling parameter.

In general, for any expression one can determine the values of $m$ and $n$ such that it is of order $O(M^nN^m) = O((MN)^mN^{m-n})$. If $m > n$, such an expression vanishes in the thermodynamic limit $N \to \infty$. Below, when adding expressions of different $M$ and $N$ orders, expressions which vanish (relatively) in the thermodynamic limit will be omitted. The remaining terms with the smallest power of $MN$ (typical $(MN)^0$) will be referred to as the leading $N$-order terms and the terms of one power higher in $MN$ will be called the leading correction terms or the first mode coupling corrections.

A. $N$-Ordering of Single Time Interval Correlation Functions. Using these principles, it was shown that the $N$-orders of the (multilinear) vertexes in eq 11 (in their maximally matched form) are

$$
M_{\alpha \beta}^{ss} \begin{cases} O(N^{(\beta-\delta)}) & \text{if } \delta < \beta \\ O(N^0) & \text{if } \delta \geq \beta \end{cases}
$$

Following these lines of analysis, the matrix $M$ in eq 11 and the normalized single-time interval correlation functions in eq 9 are, in terms of $N_{\alpha \beta} = \langle L_{Q_\alpha} \rangle Q_\alpha^T = \int_0^\beta dt \langle \phi_{\alpha}(t) \phi_{\beta}^* \rangle$

$$
M_{\alpha \beta}^{cc} \equiv N_{\alpha \beta} \ast K_{\alpha \beta}^{cc} \left[ 1 + O(N^{-1}) \right]
$$

$$
G_{\alpha \beta}^{cc}(z) = [z - M^{cc}(z)]_{\alpha \beta}^{-1}
$$

$$
G_{\alpha \beta}^{ss}(z) = [z - M^{ss}(z)]_{\alpha \beta}^{-1}
$$

from which we see that single particle modes do not contribute to the dynamics of single time interval correlation functions of the collective modes. Similarly, since the superscripts $ss$ in $M^{ss}$ in eq 25 only mean that one of the components in each of the indices of $M^{ss}$ has a single particle character while the others are collective, the collective modes do influence the dynamics of correlation functions of tagged (single) particle densities through mode-coupling corrections to transport coefficients. For instance, the generalized self-diffusion coefficient $D(k, t)$ is renormalized through the terms in eq 15 with the bare propagator replaced by the full one (see the discussion below eq 17), i.e.,

$$
\bar{D}(k, t) = D^B(k, t) + \Sigma^V(k, t)
$$

$$
\Sigma^V(k, t) = \sum_{i<j} M_{ij}^{ss} \langle N_i(k) \rangle \langle N_j(k - q) \rangle F_i(k - q, t) \times
$$

$$
G_{ij}^{cc}(k, q) \times B_i(q) \times B_j(q) \times G_{ij}^{ss}(q) \times \langle N_i(k) \rangle \langle N_j(k) \rangle + ...
$$

where $D^B = M_{11}^{ss}$ is the “bare” diffusion coefficient with weak $k$ and $t$ dependence and $F_i(k, t) = \langle N_i(k) \rangle \delta(t)$ is the self-part of the dynamic structure factor. Careful analysis of the mode-coupling contributions to tagged particle transport coefficients is essential in the derivation of observed relations between quantities such as the self-diffusion coefficient of a Brownian particle and the viscosity of the fluid.24,25

B. $N$-Ordering of Higher-Order Vertexes and Correlation Functions. The analysis of the $N$-ordering of higher-order vertexes involving mixed tagged and collective particle densities follows by induction as outlined in ref 15. Using the $N$-ordering results for the single time interval correlation functions and the relation between the single-time interval correlation functions and the multiple-time correlation functions in eq 22, one obtains the following $N$-order in the maximally matched form of the higher-time vertexes in which the central index is a linear tagged density:

$$
\bar{M}_{ijkl}^{es} = \begin{cases} O(N^{(\beta-\gamma)}) & \text{if } \gamma < \delta \\ O(N^{-1}) & \text{if } \gamma = \delta \\ O(N^0) & \text{if } \gamma > \delta \end{cases}
$$

$$
\bar{M}_{ijkl}^{cc} = \begin{cases} O(N^{(1-\delta-\gamma)}) & \text{if } \gamma < \delta \\ O(N^{-1}) & \text{if } \gamma = \delta \\ O(N^0) & \text{if } \gamma > \delta \end{cases}
$$

$$
\bar{M}_{ijkl}^{ss} = \begin{cases} O(N^{(1-\delta-\gamma)}) & \text{if } \gamma < \delta \\ O(N^0) & \text{if } \gamma > \delta \end{cases}
$$

$$
\bar{M}_{ijkl}^{ss} = O(M_{ijkl}^{ss})
$$

Furthermore, the higher order propagators $G_{ijkl}$ obey the same $N$-ordering rules as the higher-order vertexes, namely

$$
G_{ijkl} = O(\bar{M}_{ijkl})
$$

(26)

Using these results, we see that the two-time interval tagged particle correlation function (with time intervals $t_1$ and $t_2$) reduces to a particularly simple form to leading $N$-order:

$$
G_{1111}(t_2, t_1) = \langle \langle Q(k - q, t_2) Q^*_l(q, t_1) \rangle \rangle
$$

$$
= G_{11}(t_2) \bar{M}_{1111}^{es} G_{11}(t_1) + O(N^{-1})
$$

(27)

with leading order correction terms

$$
G_{1121}(t_2) \bar{M}_{1121}^{es} G_{11}^{ss}(t_1) + G_{1121}^{cc}(t_2) \bar{M}_{1121}^{cc} G_{11}(t_1) + G_{1121}^{cc}(t_2) \bar{M}_{1121}^{cc} G_{11}^{cc}(t_1)
$$

(28)

where $G_{1121}(t)$ and $G_{1121}^{cc}(t)$ are higher-order, single time interval correlation functions. Note that in eqs 27 and 28, the matrix indices as well as sums over repeated intermediate wave vectors, as more fully indicated in eq 22, have been suppressed for notational simplicity. Given the definition of $M_{1111}$ in eq 20, one sees that only the second, dissipative term in 20b contributes, which is $O(k_0^2)$. Thus, the first term in eq 30 is, in orders of $k_0$, the leading correction term, while the others are $O(k_0^2)$.

For the three-time interval correlation function, the leading $N$-order contribution is

$$
G_{111111}(t_3, t_2, t_1) = G_{1111}(t_3) \bar{M}_{1111}^{es} G_{00}(t_3) \bar{M}_{1111}^{ss} G_{11}(t_1) + G_{1111}(t_3) \bar{M}_{1111}^{cc} G_{11}(t_2) \bar{M}_{1111}^{cc} G_{11}(t_1)
$$

(29)

with the following three terms contributing at the order of the
Mode-Coupling Theory

first mode-coupling corrections:

\[
G_{ii}^{ss}(t_2)M_{111}^{ss} G_{ii}^{ss}(t_2) + \frac{G_{ii}^{ss}(t_2)M_{111}^{ss} G_{ii}^{ss}(t_2) + G_{ii}^{ss}(t_2)M_{111}^{ss} G_{ii}^{ss}(t_2)}{O(k_0^5)} (30)
\]

The \(O(k_0^5)\) correction here in fact consists of seven more correction terms, all variants of the form \(G_{ii}^{ss}(t_2)M_{111}^{ss} G_{ii}^{ss}(t_2)-M_{111}^{ss} G_{ii}^{ss}(t_2)\) and all \(O(k_0^5)\).

IV. Applications of Higher Order Correlation Functions

It is often difficult using single time-interval correlation functions to discern what features of the underlying collective dynamics of slowly relaxing systems leads to qualitative features in the relaxation profile in glassy and frustrated systems. Typically, single time-interval correlation functions in frustrated systems display nonexponential time decay, often exhibiting a two-step relaxation processes associated with caging effects and cooperative flow through heterogeneous dynamics\(^2\) on long time scales. Given the heterogeneous nature of the dynamics in such systems, it is natural to ask what type of relaxation processes lead to this nonexponential time signature.

In a series of articles,\(^4\)\(^12\)\(^11\) Heuer and co-workers have examined the information content of higher-order correlation functions to assess how detailed features of the dynamics correspond to aspects of the relaxation in glassy systems. In particular, Heuer et al. have focused on multiple-time correlation functions designed to probe relaxation type\(^1\)\(^13\) as well as rate memory\(^1\)\(^3\) associated with the persistence of slow particle motion in supercooled liquid systems. The basic idea of the multiple time correlation approach is to examine correlations of particle motion over several time intervals, separating out distance and directional correlation.\(^1\)\(^3\) In this fashion, one effectively devises time filters that extract a particular feature of the dynamics to be analyzed. The fundamental building block of the time correlation functions is the (real part of) tagged particle density at time interval \(\Delta t_0 = t_1 - t_0\) defined to be

\[
f(t_0, t_1) = \cos(k \cdot (r(t_1) - r(t_0))) \equiv \cos(k \cdot \Delta r_{01})
\]

\[
= \Re \langle \tilde{N}_1(k, t_1) \tilde{N}_1(k, t_0) \rangle
\]

whose ensemble average gives the incoherent scattering function \(F_3(k, \Delta t_0)\). Intuitively, \(F_3(k, \Delta t)\) measures the fraction of particles moving a distance less than \(2\pi/k\) over the time interval \(\Delta t\), and hence \(F_3(k, t_1)\) can be viewed as a time-filter selecting out slowly moving particles. The essential idea in identifying the relaxation type is to consider how the motion of slow particles is correlated over subsequent time intervals. In the purely heterogeneous scenario, one expects that motion in subsequent time intervals has no direction dependence (no back-and-forth motion). On the other hand, for the purely homogeneous scenario, one rules out a distance dependence in subsequent time intervals to exclude the presence of different mobilities. To characterize these limits, it is helpful to define the three-time correlation function\(^1\)\(^3\)

\[
F_3(\Delta t_{01}, \Delta t_{12}) = \langle f(t_0, t_1)f(t_1, t_2) \rangle = \langle \cos(k \cdot \Delta r_{01})\cos(k \cdot \Delta r_{12}) \rangle
\]

In the homogeneous limit, the projected distance \(k \cdot \Delta r_{12}\) along \(k\) is independent of \(k \cdot \Delta r_{01}\), and hence the three-time correlation factors to

\[
F_3(\Delta t_{01}, \Delta t_{12}) = \langle f(t_0, t_1)f(t_1, t_2) \rangle
= F_3(k, \Delta t_{01})F_3(k, \Delta t_{12})
\]

which suggests defining an indicator function for homogeneous dynamics

\[
F_3^{hom}(k, \Delta t_{01}, \Delta t_{12}) = F_3(\Delta t_{01}, \Delta t_{12}) - F_3(k, \Delta t_{01})F_3(k, \Delta t_{12})
\]

that vanishes in the homogeneous limit. On the other hand, in the case of purely heterogeneous dynamics, consider the indicator\(^1\)\(^3\)

\[
F_3^{het}(k, \Delta t_{01}, \Delta t_{12}) = F_3(k, \Delta t_{01} + \Delta t_{12}) - F_3(\Delta t_{01}, \Delta t_{12}) = -\langle \sin(k \cdot \Delta r_{01})\sin(k \cdot \Delta r_{12}) \rangle
\]

where the last equality was obtained by writing out the filter functions \(f(t_0, t_1)\) in the definition of \(F_3\) and \(F_3^{het}\) in complex representation. Since the direction of the motion in subsequent time intervals is not correlated in the heterogeneous limit, the right-hand side of eq 35 vanishes. Note that both indicator functions make use of the three-time correlation function of the tagged particle density and can be expressed in terms the multiple-time propagators of the previous section as

\[
F_3(k, \Delta t_{01}, \Delta t_{12}) = \frac{1}{2}F_3^{hom}(k, \Delta t_{01} + \Delta t_{12}) + \frac{1}{2}\langle \tilde{N}_1(k, t_0 + t_1 + t_2)\tilde{N}_1(-2k, t_0 + t_1)\tilde{N}_1(k, t_0) \rangle
\]

where the second term on the right-hand side is a special case of the more general propagator \(G_{11}^{(2)}\) in eq 27 defined with \(q = -2k\) and \(t_0 = 0\) and the tagged particle densities corresponding to the number density. Both measures of relaxation type have been successfully tested\(^26\) on simple 1-dimensional model systems in which the dynamical rules governing motion of a particle are constructed to be inherently heterogeneous (an ensemble of particles each moving with constant but different jump rates) or homogeneous (a collection of particles in which particles hop between sites with two different site-dependent rates).

As the function \(f(t_0, t_1)\) acts as a slow-dynamics filter, it can be used as a means of selecting a subensemble of the full system. As an alternative to \(F_3^{het}\) and \(F_3^{hom}\) in studying the heterogeneous nature of the dynamics, one can then examine examine how long particles that are initially in the slow-dynamics ensemble remain in this ensemble to get an idea of how long solidlike domains persist in supercooled and glassy systems. Such filters are also useful to try to rigorously map deterministic systems onto simplified models of glassy behavior, such as facilitated spin models.\(^27\)\(^32\) A suitable measure of the lifetime of solidlike domains can be defined by constructing the four-time correlation function

\[
\tilde{C}^{(4)}(t_0, t_1, t_2, t_3) = \langle f(t_0, t_1)f(t_2, t_3) \rangle
= \langle \cos(k \cdot \Delta r_{01})\cos(k \cdot \Delta r_{23}) \rangle
\]

Generally, it is sufficient to look at a time filter over a fixed period \(\Delta t = t_1 - t_0 = t_3 - t_2\), where the waiting interval \(t_2 = t_1 + \tau\) between subsequent applications of the time filter is \(\tau\).
For large waiting times \( \tau \), one expects that only a random selection of the particles initially in the slow-ensemble remain in the slow ensemble so that \( C^{(4)} \to F_1(k, \Delta t)^2 \) as \( \tau \to \infty \). It therefore is logical to focus on the fluctuation of \( f(t_0, t_1) \) defined as

\[
C^{(4)}(\Delta t, \tau) = \langle f(0, \Delta t) f(\tau + \Delta t, \tau + 2\Delta t) \rangle - F_1(k, \Delta t)^2
\]

where \( \Delta t \) is chosen to be shorter than the inverse of the (typical) relaxation rate of solidlike domains then the time scale \( \tau \) at which this decays to zero can be interpreted as the domain relaxation time.

Note that this quantity is related to the \( G^{(3)}_{1111} \), expressed in eqs 29 and 30, via

\[
C^{(4)}(\Delta t, \tau) = 1/4 G^{(3)}_{1111}(\Delta t, \tau, \Delta t) + G^{(3)}_{-1-1-1}(\Delta t, \tau, \Delta t) + G^{(3)}_{-1-11}(\Delta t, \tau, \Delta t) - F_1(k, \Delta t)^2
\]

where \( \kappa = \{N_i(k)\} \) and \( \kappa' = \{N_i(-k)\} \).

**A. Calculation of Domain Relaxation Rate and Relaxation Type Indicators.** Application of the mode-coupling theory of multiple-time correlation functions developed in section II to evaluate the domain relaxation rate via eq 37 or the relaxation type indicators defined in eqs 34 and 35 requires complete specification of the slow basis set variables. As the indicators are of significant interest in dense supercooled liquids in which the precise definitions of these variables for a hard sphere system). For this specific choice of basis set, the time-derivative of \( H(k) \) with a similar expression for \( G_{12} \).

1. Relaxation Type. Combining these results with the leading \( N \)-order expansion terms of \( G^{(3)}_{111} \) and insertion into the expression for \( F_3 \) in eq 36 yields

\[
F_3(k, t_1, t_2) = \frac{1}{2} F_1(k, \Delta t_{01} + \Delta t_{12}) + \frac{1}{2} F_1(k, \Delta t_{12}) F_3(k, \Delta t_{01}) + \frac{1}{2} F^m_3(k, \Delta t_{01}, \Delta t_{12})
\]

where \( F^m_3 \) is the first mode-coupling contribution to \( F_3 \). Note that from eq 28, we see the mode-coupling corrections involve the evaluation of terms such as

\[
\sum_{i \neq q} G^{(3)}_{111}(\hat{N}_i(k); \hat{N}_i(q - k)B_i(q); \Delta t_{12}) \ast
\]

In eq 41, the sum extends over the three hydrodynamic collective variables \( B_i(q) \) and \( G^{(3)}_{12}, G^{(3)}_{21} \) denote the multiple-point mixed tagged/collective correlation function

\[
G^{(3)}_{12}(\hat{N}_i(k); \hat{N}_i(q - k)B_i(q); t) = \langle \hat{N}_i(k, t)O_1^{(3)}(k - q, q)O_2^{(3)}(k - q, q)B_i(q) \rangle
\]

provided the collective densities are orthogonal \( (B_i(k)B_j^*) = \delta_{ij}\delta(B_i(k)B_j^*) \). Similarly, \( G^{(3)}_{21} \) is defined as

\[
G^{(3)}_{21}(\hat{N}_i(k - q)B_i(q); \hat{N}_i(k); t) = \langle O_2^{(3)}(k - q, q; t)O_1^{(3)}(k) \rangle
\]

Using the mode-order expansion eq 19, the multiple-point correlation function \( G_{21} \) can be approximately written as

\[
G^{(3)}_{21}(\hat{N}_i(k - q, q; t) = \int_0^t \sum_j \langle \hat{N}_j(k - q, q; t - \tau) M_{21}^{(3)}(k - q, q, k) \rangle F_j(k, \tau)
\]

with a similar expression for \( G_{12} \). Note that in eq 43, there is an implicit sum over collective mode index \( j \). In practice, it is often convenient to work in a basis set in which the matrix of collective linear—linear (normalized) correlation functions is
diagonal. In the hydrodynamic regime, this corresponds to choosing the $B$ set to be composed of the hydrodynamic sound and heat modes.

Returning to the problem of calculating relaxation type, inserting eq 42 into the definition of the indicator functions yields

$$ F_3^{hom}(k, \Delta t_{01}, \Delta t_{12}) = \frac{1}{2}(\Delta F_2(\Delta t_{01}, \Delta t_{12}) + F_3^{mc}) \quad (44) $$

$$ F_3^{het}(k, \Delta t_{01}, \Delta t_{12}) = \frac{1}{2}(\Delta F_2(\Delta t_{01}, \Delta t_{12}) - F_3^{mc}) \quad (45) $$

where

$$ \Delta F_2(\Delta t_{01}, \Delta t_{12}) = F_s(k, \Delta t_{01} + \Delta t_{12}) - F_s(k, \Delta t_{01})F_s(k, \Delta t_{12}) \quad (46) $$

In the hydrodynamic limit, ignoring mode-coupling effects, one expects that an exponential decay of the intermediate scattering function of the form $F_s(k, t) \sim e^{-Dk^2t}$, where $D$ is the self-diffusion coefficient. In this case, $\Delta t_{01} = 0$ and both indicators are approximately zero. On the other hand, if $F_s(k, t)$ has a nontrivial relaxation profile, perhaps of the form of a stretched exponential $F_s(k, t) \sim e^{-\beta t^\alpha(k)t^\beta}$, where $\beta$ is the stretching exponent, then $\Delta F_2 \neq 0$. It is therefore evident that mode-coupling effects are absolutely essential to distinguish between homogeneous and heterogeneous types of nonexponential relaxation. Although this result is obvious since mode-coupling must be invoked to give rise to nonexponential relaxation in the first place, it is the difference in the time dependence of $\Delta F_2$ and the mode-coupling corrections $F_3^{mc}$ that allows one to distinguish between the two relaxation types. On the molecular scale, one also anticipates a contribution to these expressions from the dissipative part of $M_{111}$ that corrects the simple factorization result at lowest N-order

$$ \langle \hat{N}_1(k - q, t_1 + t_2)N_1(q, t_1)\rangle \approx F_s(k - q, t_2)F_s(k, t_1)[1 + O(k_0^2)] \quad (47) $$

Note that the effect of these corrections is not to modify the time behavior but to modify the wave vector dependence on the right-hand side of eq 47. This modification only makes sense when $t_1$ and $t_2$ are large compared to the microscopic relaxation time $t_m$ corresponding to the time scale after which the instantaneous approximation implicit in eq 21 is valid.

2. Domain Relaxation. The rate of domain relaxation can be similarly calculated using the N-ordering scheme to simplify the multiple-time correlation functions in eq 37. Using the form of the higher-order vertexes in the hydrodynamic limit and $G_{00} = 1$, $G_{11}(\hat{N}_1(k = 0); \hat{N}_1(k = 0); \tau) = 0$, and $G_{11}^\alpha(\hat{N}_1(k); \hat{N}_1(k); \Delta t) = F_s(k, \Delta t)$, one obtains

$$ G_{33}^\alpha_{333}(\Delta t, \rho, \Delta t) \approx F_3(k, \Delta t)F_3(k, \Delta t) \quad (48) $$

The same holds for the other four time correlations in eq 37, therefore the leading orders of the multiple-time correlations are canceled by the last term in eq 37, so that leading order $C^{(1)}(\Delta t, \rho)$ is zero. The first nonzero contribution arises at first mode-coupling order, as given by eq 30. However, the terms in that equation that involve $G_{21}(\hat{N}_1(q), B_s(-q); \hat{N}_1(0); \rho)$ are zero because $\hat{N}_1(0) = 0$. Thus, only the last term from eq 30 survives. Taking together the contributions from the four higher-order terms in eq 37 and using the fact that $G_{11}^\alpha$ factorizes to leading order, one obtains the mode coupling result

$$ C^{(1)}(\Delta t, \rho) = Re\sum_{i\neq j} G_{11}^{2i}(\hat{N}_1(q), \hat{N}_1(q - q)B_s(q); \Delta t) \times $$

$$ \times F_{\sigma}(q, \rho)G_{11}^{1j}(q, \rho) \times $$

$$ G_{21}^\alpha(\hat{N}_1(k - q)B_s(q); N_s(k); \Delta t) + O(k_0^2) \quad (49) $$

where eq 43 may be used for $G_{11}^{1j}$ and $G_{11}^{2j}$.

As this result already somewhat suggests, for dense, supercooled liquids, one anticipates that the conversion time of solidlike domains to liquidlike domains of typical length scale $l \approx 2\pi/\eta k$ also occurs on time scales corresponding to the wave vector-dependent $\alpha$-relaxation time of $F_s(k, \rho)$.

B. Numerical Analysis of Multiple-Time Correlation Functions of Tagged Densities in a Hard Sphere System.

To validate the mode-coupling theory approach to multiple-time correlation functions of collective densities, extensive simulations of a hard sphere system at moderate densities were carried in ref 35. It is straightforward to extend these simulations to incorporate calculations of tagged particle densities to test the simple factorization result for multiple-time correlation functions of the tagged particle number density in eq 47 and to examine how well the theory predicts higher-point correlation functions of mixed tagged/collective densities that are necessary to compute the mode-coupling corrections to the leading N-order factorization. All simulation results presented in this section were obtained using the simulation methodology described in detail in ref 35 on a hard sphere system of a relatively low reduced density $\rho^* = \rho \rho_s = 0.1$, where $\rho_s$ is the density at close packing.

The size of the periodic system was chosen to have cubic box lengths $L_x = L_y = L_z = 47.30631$ such that the simulation system contained $N = 15000$ hard sphere particles of mass $m = 1$ and diameter $a = 1$ at the chosen density. For this system size, the smallest dimensionless wave vector $k_{\text{sd}} = 2\pi a L_x = 0.13273$ so that all quantities examined are roughly in the hydrodynamic regime. For this system, the mean collision time calculated from the Enskog theory is approximately $t_c = 1.42417$ at an inverse temperature $\beta = 3$, while the mean-free path is $l_c = 1.85561$ so that $k_{\text{sd}} = 0.246305$. Under these conditions, the estimated relaxation time of $F_s(k_0, t)$ is $t_\rho \sim (Dk_0^2)^{-1} \sim 0.3 t_c$, where $D = 0.725586$ is the self-diffusion coefficient calculated from the Enskog theory result

$$ D = \frac{3w_s}{8\sqrt{\beta mn\rho(\rho^2)a^2}} \quad (50) $$

where $w_s = 1.01896$ and $g(a)$ is the radial distribution function at contact. For a hard sphere system, $g(a)$ can be estimated using the Carnahan-Starling equation of state

$$ \frac{\beta \rho}{\rho} = 1 + \frac{\eta^2}{(1 - \eta)^2} = 1 + \frac{b g(a)}{\rho} \quad (51) $$

where $b = 2\pi a^3/3$ and $\eta = \pi a^3/6$. The simulations were run for total time of approximately 1200 $t(\rho_0)$ to ensure reasonably good statistics. Following ref 35, statistical uncertainties were estimated using the symmetry properties of the correlation functions. In this approach, the statistical uncertainty for a real correlation function was constructed from a histogram of the values of the imaginary part of the complex correlation function, which vanishes on average, to determine the 96% confidence intervals. To simplify the comparison between theoretical predictions and the simulation results, all wave vectors were
taken to be collinear so that $k \cdot q = kq$. To further improve statistics, the wave vectors were independently taken along the three principal directions $\hat{x}$, $\hat{y}$, and $\hat{z}$ of the cubic simulation box and averaged.

1. Two Time-Interval Correlation Function. One of the central results of section 4, the simple factorization of multiple-time correlation functions of the tagged particle number density (see eq 49) is simple to verify numerically. To validate this prediction, numerical calculations of the correlation function $g^{(2)}(t_1, t_2) = \langle \hat{N}(k - q, t_1 + t_2)\hat{N}(q, t_1)\hat{N}^\ast(k) \rangle$ were computed as a function of wave vector combinations $(k, q) = (m, n)\mathbf{k}_0$ for $m$ and $n$ values ranging from 1 to 3 with $m = n$. To simplify the comparisons, three different time cross sections ($t_1$, $t_2$ for each pair $(m, n)$ were calculated, namely $(t, t)$, $(t, 3t)$ and $(3t, t)$. These particular choices of $t_1$ and $t_2$ are the simplest to implement when simulation data is stored in standard linear array data structures. The results, shown in Figure 1, show that the product $g^{(2)}(k - q, t_1 ; t_2)F_0(k, t_1)$ approximates $g^{(2)}(t_1, t_2)$ very well for all choices of wave vector combinations and all time cross sections. However, given that the statistical uncertainties for both $g^{(2)}$ and $g^{(2)}$ are on the order of 0.002, it is clear that the numerical results indicate a small but systematic difference between these two quantities which reaches a maximum a short times $t \sim \mathcal{O}_d$, as can be seen in the panels on the right-hand side of Figure 1.

This difference should be well-reproduced by the mode-coupling correction term in eq 41, although this has not yet been verified.

2. Multiple-Point Correlation Function. Although it is certainly possible to calculate the leading order mode-coupling correction term in eq 41 analytically using hydrodynamic forms for the collective correlation functions $G^{(2)}(t)$, the calculation is tedious due to the sum over different collective modes $B$. However, to validate the applicability of the mode-coupling theory in the calculation of the first order correction terms $F_1$, we examine the quality of the predicted form of the multiple-point correlation function

$$G^{(2)}_{g f}(\mathbf{k} - \mathbf{q}, t) \equiv \langle \hat{N}(\mathbf{k} - \mathbf{q}, t)\hat{N}(\mathbf{q}, t)\hat{N}^\ast(\mathbf{k}) \rangle - \frac{S(\mathbf{q})}{\langle N \rangle} F_1(k, t) \quad (52)$$

where $S(\mathbf{q}) = \langle \hat{N}(\mathbf{q})\hat{N}^\ast(\mathbf{q}) \rangle$ is the static structure factor, against direct numerical calculation (note: in eq 52 we took the thermodynamic limit). From eq 43, we see that this correlation function is approximately given by

$$G^{NN}(\mathbf{k} - \mathbf{q}, t) = \int_0^t dt F_1(k, t - t') \times G^{NN}(t) + G^{NN}(t)F_1(k, t) \quad (53)$$

where $B_j$ runs over the set $\{N, P, H\}$ or some variant of it. Note that with this choice of collective densities, the computation of eq 53 requires the calculation of 3 coupling vertexes $M^{NN}_{g f}, M^{P P}_{g f}$, and $M^{H H}_{g f}$, as well as the input of the collective linear—linear time correlation functions $G^{NN}_{g f}, G^{P P}_{g f}$, and $G^{H H}_{g f}$. In principle, analytical forms of the $G_{11}$ time correlation functions can be utilized in the hydrodynamic regime with transport coefficients either fitted from simulation data or taken from kinetic theory. Given the simplicity and ease of numerically calculating the $G_{11}$ with excellent precision, we have chosen to evaluate the convolution integrals in eq 53 by numerically integrating simulation data using a version of Simpson’s rule that allows interpolation of data. From time-inversion symmetry, $M_{g f} = 0$ for $B_j = N$ or $H$, and it is evident that the only coupling at “Euler” order arises for $B_j = P$. However, as noted for the case of multiple-point correlation functions of purely collective densities in ref 35, the inclusion of the additional couplings to $N$ and $H$ arising at “dissipative” order $M_{g f}^{NN}$ is essential if quantitatively accurate predictions are desired. It may appear at first glance that the dissipative contributions are negligible in the limit of small wave vectors since they introduce additional factors of $k_0$. In fact the overall order of the multiple-point correlation functions is determined by a wave vector-dependent prefactor multiplied by the convolution of the two-point, single time interval correlation functions $G_{11}$. The time convolution of these correlation functions can give rise to additional factors of wave vector depending on their symmetry properties, so that the overall contribution of the $P$, $N$ or $H$ coupling are comparable in magnitude.

The evaluation of the dissipative contribution to coupling vertexes $M^{NN}_{g f}$ and $M^{H H}_{g f}$ requires external input. In the Appendix, these vertexes are evaluated in the small wave vector limit by relating the dissipative vertexes to the Enskog self-diffusion coefficient and its derivatives with respect to thermodynamic parameters. The predictions are therefore free of any adjustable parameters and constitute a rigorous test of the mode-coupling theory. The results of the comparison are shown in Figure 2.

Note that although the data are a bit noisy, the theoretical predictions generally fall within the confidence intervals of the simulated data except at very short times $(t \sim 2\tau)$ where one expects the theory to break down due to the instantaneous approximation of the coupling vertexes.

V. Summary

In this paper, a mode-coupling theory was presented in which multiple point and multiple-time correlation functions for collective densities and tagged particle densities are expressed...
in terms of ordinary two-point, single-time interval correlation functions and a set of vertexes. The theory developed here does not assume that fluctuating forces (noise) are Gaussian distributed and, in principle, does not require an ansatz to obtain self-consistent equations. Furthermore, unlike kinetic theories, it is not restricted to low densities and should be applicable to dense fluids where cooperative motions of particles and collective modes are important.

The formalism is based on projection operator techniques, which, for ordinary two-point, single-time correlation functions, lead to a generalized Langevin equation in which the memory function decays on a microscopic time scale (eq 6). The simple extension of the projection operator formalism to multiple-time correlation functions of tagged particle densities is complicated by the fact that the fluctuating forces appearing in the generalized Langevin equation do not obey Gaussian statistics. Furthermore, multiple-time correlations of the fluctuating force can in fact have a slow decay when the time arguments of these forces become comparable. To treat multiple-time correlation functions of fluctuating forces properly, the correlation functions were manipulated so that the time arguments of all fluctuating forces appearing in the correlations were guaranteed to be well-separated, ensuring that all memory functions which arise in the mode-coupling theory decay to zero on a molecular time scale. This construction allows equations which are local in time to be obtained which relate the multiple-time correlation function to two-time but multiple-point correlations coupled by essentially time-independent vertexes. These expressions, in turn, can be written as convolutions of two-point, single time interval “propagators” coupled by time-independent vertexes. These propagators can either be taken directly from experiment, simulation, or can be solved self-consistently within the mode-coupling formalism. The vertexes, which are composed of a static part (Euler term) and a generalized transport coefficient, can similarly be calculated from kinetic theory or taken from molecular dynamics and Monte Carlo simulations.

The equations for higher-order correlation functions contain an infinite sum of terms which can be made tractable for systems with a finite correlation length by applying a cumulant expansion technique pioneered by Oppenheim and co-workers$^{9,21,22}$ termed the $N$-ordering method. The method was applied to obtain the leading order and first mode-coupling corrections of expressions for tagged-particle density multiple-time and mixed tagged/collective particle density multiple-point correlation functions designed to probe detailed aspects of the relaxation profile of glassy systems.

The mode-coupling theory outlined here is the first step toward a fully microscopic theory applicable to molecular length scales that enables one to analyze the mapping of the dynamics in deterministic glassy systems to stochastic spin model of glasses, as well as to define subensembles via filters based on dynamical and spatial properties to probe dynamic heterogeneities, clustering properties and many other aspects of the dynamics of frustrated systems.

Acknowledgment. It is a pleasure to dedicate this paper to Irwin Oppenheim, whose friendship we greatly treasure. This work was supported by a grant from the Natural Sciences and Engineering Research Council of Canada. J.S. would like to thank Walter Kob and the Laboratoire des Colloı¨des, Verres et Nanomatériaux in Montpellier, France, for their hospitality and the CNRS for additional funding during the final stages of this work.

Appendix: Evaluation of the Mode-Coupling Vertexes

As mentioned in the main text, the vertexes required for the calculation of the mode-coupling correction to the factorization of the multiple-time correlation function $F_2(t_1, t_2)$ are $M_2^{(N,N)}$, $M_2^{(N,N)}$, and $M_2^{(N,N)}$, where the general form of the vertex $M_2^{(N)}$ is

$$M_2^{(N)} = M_2^{(N)} + M_2^{(N)}$$

and

$$M_2^{(N)} = \langle L Q_1(t) Q_1(t) K_{11}^{\alpha} \rangle$$

where $M_2^{(N)}$ is referred to as the “Euler” contribution to the vertex, $M_2^{(N)}$ is the “dissipative” part of the vertex, and $Q(t)$ is the fluctuating force defined in eq 10.

Examining first the Euler contributions $M_2^{(N)}$, we note that since $\langle L Q_1(t) Q_1(t) \rangle = 0$, we have

$$M_2^{(N)}(\hat{N}_1(k-q)B(q); \hat{N}_1(k)) = \frac{i}{m} \langle L Q_1(t) \hat{N}_1(k-q), B(q) \rangle P_1(k)k$$

From the time-reversal symmetry properties of the correlation functions, we see that $M_2^{(N)} = 0$ for $B = N$ and $B = H$, and for $B = P$, we find

$$M_2^{(N)}(\hat{N}_1(k-q)P_1(q); \hat{N}_1(k)) = \frac{ik\hat{q}}{\beta}$$

Evaluation of the dissipative vertexes $M_2^{(N)}$ requires the calculation of the linear $q_1$ and bi-linear $q_2$ fluctuating forces. For the linear fluctuating force, we have (in the thermodynamic limit)

$$q_1(r, t) = e^{p_1 t}P_1 \frac{1}{m} \hat{N}_1(k)$$

and the bi-linear fluctuating force is

$$q_2(k-q, q; t) = e^{p_1 t}P_1 \frac{1}{m} Q_1(k-q, q)$$

Figure 2. Comparison of simulated (unconnected dots) and predicted (solid lines) values of $G_2(t)$ as a function of $t$. The results in the top row correspond to wave vectors pairs (1, 2) and (2, 1) from left to right, those in the middle row correspond to (1, 3) and (3, 1), and those in the bottom row correspond to (2, 3) and (3, 2).
where $P^\perp$ is a projection operator that projects onto a subspace orthogonal to that spanned by the multilinear basis set $Q_\alpha$. Noting that (in the thermodynamic limit)

$$Q'_2(\hat{N}_1(\mathbf{k}-\mathbf{q})\hat{N}(\mathbf{q})) = \hat{N}_1(\mathbf{k}-\mathbf{q})\hat{N}(\mathbf{q}) - \frac{S(\mathbf{q})}{\langle N \rangle}\hat{N}_1(\mathbf{k}),$$

$$Q'_2(\hat{N}_1(\mathbf{k}-\mathbf{q})P_\mu(\mathbf{q})) = \hat{N}_1(\mathbf{k}-\mathbf{q})P_\mu(\mathbf{q})$$

and $P^\perp\hat{N}_1(\mathbf{k}-\mathbf{q})P_\mu(\mathbf{q}) = 0$, we see that, at $t = 0$, the bilinear fluctuating forces are

$$q'_2\dot{\hat{N}}_1(\mathbf{k}-\mathbf{q})\hat{N}(\mathbf{q}) = \frac{i(k-q)}{m}P_1(\mathbf{k}-\mathbf{q})\hat{N}(\mathbf{q}) - \frac{S(\mathbf{q})}{\langle N \rangle}\frac{i}{m}P_1(\mathbf{k})$$

$$q'_2\dot{\hat{N}}_1(\mathbf{k}-\mathbf{q})P_\mu(\mathbf{q}) = \frac{i(k-q)}{m}P^\perp_1(\mathbf{k}-\mathbf{q})P_\mu(\mathbf{q})q +$$

$$P^\perp\dot{\hat{N}}_1(\mathbf{k}-\mathbf{q})L P_\mu(\mathbf{q})q$$

Inserting these results into the expressions for the dissipative vertices and expanding the resulting expressions in powers of the base wave vector $k_0$, one finds

$$M^{N,N_1}_2 = -\frac{(k-q)^2 k^2}{m^2}\int_0^\infty d\tau \langle P_1(\tau)P_\mu(\tau) \rangle$$

and

$$M^{N,N_1}_2 = O(k_0^3)$$

where we have defined $iq\cdot j_\mu = -2\beta/\sqrt{6}$ $P^\perp\dot{L}\hat{E}(\mathbf{q})$. Noting that the Green-Kubo expression for the self-diffusion coefficient $m^2D = \int_0^\infty d\tau \langle \dot{P}_1(\tau)P_\mu(\tau) \rangle$ and that $\langle \Delta \hat{N} \rangle = \delta(\Delta)\delta(\beta\mu)$ and $\langle \Delta \hat{E} \rangle = -\delta(\Delta)\delta(\beta\mu)$, where $\mu$ is the chemical potential of the system, allows us to write

$$M^{N,N_1}_2 = -\frac{(k-q)^2 k^2}{m^2}\int_0^\infty d\tau \langle j_\mu(\tau)P_\mu(\tau) \rangle$$

The dissipative vertex $M^{N,N_1}_2$ contains a new transport coefficient $\int_0^\infty d\tau \langle j_\mu(\tau)P_\mu(\tau) \rangle$ which could, in principle, be evaluated by doing a short-time expansion or using uncorrelated collisions in a kinetic theory. Nonetheless, we expect this contribution to be very small since $\langle j_\mu(\tau)P_\mu(\tau) \rangle$ is strictly zero due to the projection operator $P^\perp$. In the numerical work in the main text, we have set this term to zero.

Using the Enskog form for the self-diffusion coefficient and the Carnahan—Starling equation of state, we find that

$$\frac{\partial D}{\partial \beta\mu} = -\frac{D}{g(a)}\frac{\bar{\eta}(2\bar{\eta} - 5)}{(1 - \bar{\eta})^2}$$

$$\frac{\partial D}{\partial \beta\mu} = -\frac{D}{2\beta} + \frac{D}{g(a)}\frac{\bar{\eta}(2\bar{\eta} - 5)}{(1 - \bar{\eta})^2}$$

(A.7)

Thus, the $M_{21}$ vertexes used in the main text are

$$M^{\mu,N_1}_2 = \frac{\bar{\eta}(2\bar{\eta} - 5)}{\langle N \rangle}\frac{\delta(\beta\mu)}{2(1 - \bar{\eta})^2}$$

$$M^{\mu,N_1}_2 = \frac{D(k-q)^2}{\sqrt{6}}$$
